ABSTRACT Selectins are adhesion receptors that normally recognize certain vascular mucin-type glycoproteins bearing the carbohydrate structure sialyl-Lewis\(^y\). The clinical prognosis and metastatic progression of many epithelial carcinomas has been correlated independently with production of tumor mucins and with enhanced expression of sialyl-Lewis\(^y\). Metastasis is thought to involve the formation of tumor-platelet-leukocyte emboli and their interactions with the endothelium of distant organs. We provide a link between these observations by showing that P-selectin, which normally binds leukocyte ligands, can promote tumor growth and facilitate the metastatic seeding of a mucin-producing carcinoma. P-selectin-deficient mice showed significantly slower growth of subcutaneously implanted human colon carcinoma cells and generated fewer lung metastases from intravenously injected cells. Three potential pathophysiological mechanisms are demonstrated: first, intravenously injected tumor cells home to the lungs of P-selectin deficient mice at a lower rate; second, P-selectin-deficient mouse platelets fail to adhere to tumor cell-surface mucins; and third, tumor cells lodged in lung vasculature after intravenous injection often are decorated with platelet clumps, and these are markedly diminished in P-selectin-deficient animals.

Most human cancers are of epithelial origin, and most deaths resulting from such carcinomas are caused by tumor spread to distant organs (metastasis). Metastasis is a multistep cascade involving many factors favoring survival of the “fittest” cells that enter the bloodstream, successfully evade host defenses, bind to the endothelium of distant organs, and invade and colonize these sites (1–3). Substantial evidence indicates that platelets and leukocytes interact with hematogenously borne tumors cells, which are thought to create tumor microemboli, facilitating arrest in distant organs and subsequent interactions with endothelial cells (3–5). A reduction in circulating platelets can reduce experimental metastasis in mice (3, 4), and the relevant platelet interactions seem to involve carcinoma cell-surface glycoproteins (3, 5, 6). The molecular basis of these proposed tumor cell–platelet interactions remain largely unexplained.

Alteration of cell-surface carbohydrates is a universal phenotype of cancer cells (7–13). Cancer sialomucins are large anionic molecules thought to act as antiadhensins, preventing cell–cell interactions, e.g., with host cytotoxic cells (14–16). Inhibition of cancer sialomucin O-glycosylation can diminish metastasis formation in mouse models (11, 17). Among the carcinoma-associated glycans, the expression of sialyl Lewis\(^a\) (sLe\(^a\)) and sialyl Lewis\(^a\) (sLe\(^a\)) consistently correlates with tumor progression, metastatic spread, and poor prognosis (18–27).

The selectins are well characterized vascular receptors for certain sLe\(^a\)-containing, mucin-type glycoproteins (28–33). P-selectin expressed on activated endothelium tethers PSGL-1 on leukocytes under flow conditions, initiating rolling, and eventually resulting in leukocyte arrest on the endothelium. L-selectin on other leukocytes can also interact with PSGL-1 on such arrested cells and/or with appropriately glycosylated ligands on the endothelium (30–32). P-selectin on activated platelets also can mediate interactions with monocytes, initiating paracrine-signaling mechanisms amplifying inflammatory processes, as well as inducing tissue factor secretion, thus triggering thrombosis. E-selectin expression on endothelial cells is induced hours after initiation of inflammation and sustains leukocyte recruitment. Various lines of evidence indicate that sLe\(^a\)/a oligosaccharides are essential for generating most normal selectin ligands (29–33). However, these glycans themselves are not sufficient for high-affinity recognition. For example, PSGL-1 cannot function as an L- or P-selectin ligand, unless the apomucin backbone has sLe\(^a\)-bearing chains in close proximity to a cluster of sulfated tyrosine residues.

Because sLe\(^a\)/a structures also are commonly expressed on carcinoma cells and are associated with poor clinical prognosis, investigators initially hypothesized that E-selectin expressed on endothelium might mediate the seeding of cancer cells into metastatic sites (25, 34–36). Indeed, many human colon cancer tissues and cells do express potential E-selectin ligands (37), and artificial overexpression of E-selectin in the liver of transgenic mice redirected the metastases of tumor cells that normally colonize the lung (38). However, this hypothesis does not include a role for platelets or leukocytes. P-selectin is a more logical candidate to mediate multiple interactions involving platelets, leukocytes, endothelium, and carcinoma cells, including the microthrombi and microemboli characteristic of mucin-producing carcinomas (3, 4). Indeed, P-selectin ligands have been detected on several human carcinomas and cell lines (37, 39, 40) and are suggested to play a role in metastasis. However, there has been no in vivo confirmation of a pathophysiological role for P-selectin in cancer biology. Here, we have generated P-selectin-deficient mice in a Rag2−/− background, allowing the study of the role of P-selectin in tumor growth and metastasis.

MATERIALS AND METHODS

Production and Characterization of P-Selectin:Rag2 Double Null Mice. Female Rag2−/− mice (41) in a 129 background (Taconic) were mated with male P-selectin−/− mice (42) in a C57/B1 background (The Jackson Laboratory). F1s were crossed and their offspring were genotyped for Rag2 null mutants and P-selectin−/− null mutants. For Rag2 genotyping, rag2a—GGGAGGACACTCACTTGCCAGTA, rag2b—

Abbreviations: sLe\(^a\), sialyl Lewis\(^a\); sLe\(^a\), sialyl Lewis\(^a\);

AGTCAGAGGTCTCCATCTCAGTA, and neoA—CCGGAGAAACCCTGCGTCA were used as primers in PCR at 55°C annealing temperature (43). For P-selectin, genotyping psel—TTGTAATCTCAGAGGGAGTTG, pselb—AGGTACTTTCCTGAGTATCTCC, and neoB—CAGGACTAGTTGACGTG were used (42), at 60°C annealing temperature. Double null mutants were backcrossed to Rag2 −/− mice in 129/J background and their F1 offspring were crossed against each other to generate double null animals in a predominantly 129/J background. Control Rag2 −/− mice were generated similarly from F1 generations. Double null mice were phenotyped for mature lymphocytes in peripheral blood by staining with phycoerythrin-conjugated anti-CD4- or anti-CD8-antibodies (Caltag, South San Francisco, CA) and analysis in a FACSscan (Becton-Dickinson), with appropriate controls. Frozen sections of lung tissues were fixed in formalin, blocked with 10% goat serum with appropriate controls. Frozen sections of lung tissues were embedded sections of some tumors were blocked for nonspecific binding with 10% goat serum and 1% BSA in PBS, and incubated with biotinylated anti-mouse P-selectin antibody (PharMingen) at 5 μg/ml in PBS/1% BSA for 1 hr, followed with streptavidin-peroxidase at 1 μg/ml in PBS/1% BSA for 30 min. Conjugates were detected with metal-enhanced dianaminobenzidine tetrahydrochloride substrate (Pierce).

**Tumor Growth Assays and Survival Curves.** The human colon cancer cell lines LS180 and T-84 were passaged in αMEM media with 10% FCS. Cells (1 × 10⁶) were detached with 5 mM EDTA/PBS, disaggregated into single-cell suspensions, and injected s.c. into the lower flanks of 6- to 7-week-old mice rather than nude mice, because the xenograft model system, it is necessary to use immune-deficient mice that can accept transplanted human cells. We chose Rag2 null mutants. All previously characterized colon carcinoma lines expressing SLEx and P-selectin ligands are of human origin. To study these cells in a model system, it is necessary to use immune-deficient mice that can accept transplanted human cells. We chose Rag2 −/− mice rather than nude mice, because the defect causes a specific deficiency of mature lymphocytes (41).
without directly affecting other tissues. Because the Rag2 and P-selectin genes are on separate chromosomes and both null mice are fertile, double null mutants and control P-selectin +/+ Rag2 −/− mice were obtained by mating as described in Materials and Methods (Fig. 1A). These animals showed an absence of peripheral CD4+ and CD8+ lymphocytes (Fig. 1B) and an absence of P-selectin on lung endothelium (Fig. 1C). The mice were viable, with no gross defects, and appeared healthy when housed in a specific pathogen-free environment with controls.

Absence of P-Selectin Slows the Rate of Tumor Growth. LS180 colon carcinoma cells that express potential ligands for all three selectins (37) were used for xenotransplantation. Initial studies in Rag2 −/− mice showed that ~10^5 s.c. injected cells became a palpable tumor within 2 weeks and grew rapidly in size thereafter. We next studied groups of 6- to 7-week-old Rag2 −/− mice that were either wild-type or null for P-selectin (Fig. 2A). Tumor growth rate was reduced significantly in the absence of P-selectin. Occasional tumors in P-selectin null mice even showed regression and regrowth (data not shown). Histologically, there were no obvious differences in general appearance, extent of vascularization, or the level of infiltrating neutrophils and mononuclear cells (data not shown). P-selectin ligand expression in the tumors was confirmed by probing sectioned tissues with soluble recombinant P-selectin (data not shown). Prolonged follow-up was not possible because overall tumor bulk, weight loss, and occasional local ulceration exceeded institutional guidelines, requiring termination of the experiments. Statistically significant differences in tumor growth rates were demonstrated before the onset of any regression phenomena or any animal deaths (at 30 days, see Fig. 2B).

The timing of death of each mouse was not related to the size of the primary tumor. A trend toward improved survival was seen in the P-selectin-deficient group (Fig. 2C), up to the point where some tumors reached a size requiring termination of the experiment to comply with institutional guidelines. At this point, the remaining mice were sacrificed and their lungs were examined. In general, the P-selectin +/+ mice appeared noticeably sicker than the P-selectin −/− ones. Three independent observers noted that the wild-type mice were more cachetic, less mobile, and less well groomed than their mutant counterparts. The reason for this difference is unclear, but suggests that P-selectin affects some aspects of the biology of the cancer other than tumor size. Autopsies revealed direct peritoneal invasion in half of the mice; all the other organs looked grossly normal. Histological examination showed interstitial pneumonia in some animals of both groups, with metastatic tumor cells dispersed throughout the lung (data not shown). Occasional metastases also were visualized histologically in other organs, such as the liver, pancreas, and lymph nodes. Although there was a trend toward increased frequency of these metastases in the wild-type mice, the experiment could not be continued long enough to be certain (because of the rapid primary tumor growth rate in the wild-type animals, see above). Similar reductions in primary tumor growth rate also were seen with another colon carcinoma cell line, T-84, which expresses P-selectin ligands (ref. 37; data not shown).

P-Selectin Increases Experimental Micrometastasis to the Lung. Although the difference in primary tumor growth rate is interesting, it disallows testing of the original hypothesis regarding the role of P-selectin in metastasis (a decrease in primary tumor growth rate could reduce directly the rate of spontaneous metastasis). Therefore, we used intravenous (“experimental”) metastasis assays. LS180 cells were injected intravenously into the tail vein of 6- to 7-week-old mice. After 4 weeks, most P-selectin +/+ mice (seven of nine) developed palpable lumps around the cervical area, both dorsally and ventrally, whereas only two of nine P-selectin −/− mice developed similar masses. Generally, the wild-type mice also appeared sicker, with diminished grooming and mobility. Upon dissection, the masses were found to be enlarged lymph...
nodes containing tumor cells, or tumors growing within histologically undefined subcutaneous tissue. The lungs from both groups of mice showed some infiltrating macrophages, but no grossly visible metastatic nodules. However, in eight of nine P-selectin

1

y

1

mice, scattered tumor cells and microscopic nodules were seen in the lung parenchyma (Fig. 3A), whereas only one P-selectin

2

y

2

mouse showed such histological evidence of metastasis (Fig. 3B). Other organs were not obviously affected.

To better quantitate the lung micrometastasis, the right lung from each mouse was homogenized and total genomic DNA was purified and screened for the presence of human DNA using PCR primers that recognize human-specific Alu sequences (44). Lungs from uninjected mice were used as negative controls. PCR products were blotted onto membranes and probed with labeled oligonucleotides that hybridize to nested regions of the Alu PCR product. Signals quantified with a PhosphorImager showed that wild-type mice had significantly more human DNA in the lung than the P-selectin

1

counterparts, where only two specimens were even clearly positive (Fig. 3C). These results show that P-selectin is involved at some step in the colonization of hematogenously borne tumor cells into the lungs.

P-Selectin Facilitates the Initial Seeding of Metastatic Cells in the Lung. To explore the initial step of seeding of cells into the lung, LS180 cells were metabolically radiolabeled with

3H

thymidine and injected as single-cell suspensions into the tail veins of mice. After 3 hr, various organs were collected and radioactivity was quantitated. In general, radioactivity in the lung and some other organs was decreased in P-selectin-deficient mice. Fig. 4 shows that the presence of P-selectin facilitates the selective accumulation of injected tumor cells into the lung and, to a lesser extent, into the liver and kidney. These data show that the initial seeding of hematogenous cells to a metastatic site can be at least partly P-selectin-dependent.

P-Selectin Mediates in Vitro Rosetting of Mouse Platelets with Tumor Cells via Cell-Surface Mucins. To explore whether P-selectin on mouse platelets has a role in the initial seeding of tumors cells to the lung, we labeled freshly isolated mouse platelets with calcein and applied them to the LS-180 cells

in vitro

. As seen in Fig. 5, wild-type platelets activated with...
thrombin rosetted on the tumor cells, and this interaction was abolished by calcium chelation or by pretreatment of the tumor cells with OSGPase, which selectively cleaves mucins from the cell surfaces. Platelets from P-selectin-deficient mice do not show any rosetting, indicating that the mucin-dependent interaction is mediated primarily by P-selectin.

**Optimal in Vivo Interactions of Tumors Cells with Platelets Requires P-Selectin.** To examine these platelet:tumor cell interactions *in vivo*, we intravenously injected tumor cells (calcine-labeled or unlabeled) into mice and collected blood samples at 5, 10, 15, and 20 min postinjection. Although we detected some tumor cells remaining in the bloodstream (by fluorescence, or by Wright–Geimsa-stained blood smears), it was impossible to study their interaction with platelets. This is because all of the standard methods of anticoagulation (EDTA, citrate, or heparin) can themselves disrupt P-selectin-dependent interactions. We tried to make blood smears very rapidly after collection and/or to rapidly fix the blood cells in formaldehyde. However, in both cases, we were unable to avoid massive clumping of platelets that apparently was induced by the injury involved in the blood collection.

Therefore, we examined the tumor cells that were actually lodged in the blood vessels of the lung. Tumor cells (calcine-labeled or unlabeled) were injected intravenously, the mice were sacrificed at short time points postinjection, and the lungs were studied by frozen and/or paraffin-embedded sections. In the latter sections, unlabeled tumor cells were lodged in the capillaries of the lung, sometimes surrounded by fibrinous material (data not shown). However, the resolution was not sufficient to be certain that platelets were present in these complexes. Therefore, we obtained frozen sections of lungs after injection of calcine-labeled tumor cells and stained them with anti-CD41, a defined marker for platelets in the mouse. With this double-color-fluorescence approach, clumps of platelets could be seen attached to about half of the tumor cells in the lungs of wild-type mice. In about one-third of cases, the platelets were present in very large clumps that almost covered the tumor cells (see Fig. 6 for an example). In contrast, platelets rarely were associated with the tumor cells in the lungs of P-selectin-deficient mice (≈10% of cells). Even when found, these did not consist of the heavy clumps seen in many of the wild-type lungs.

**Discussion**

In many carcinomas, metastatic cells are enriched in sialylated Lewis blood group antigens (8, 10, 12, 25). Here we show that P-selectin, an endogenous lectin that can recognize SLEx-containing mucins, is used by the tumor cells to promote their progression to the metastatic phenotype. The experimental metastasis assay indicates that P-selectin aids the colonization of hematogenously borne colon cancer cells in the lungs of the mice. The homing assay shows that this is partially because of improved initial seeding of cells into the lung. This hypothesis is strengthened by finding that mouse platelets interact with the carcinoma cell surface mucins in a P-selectin-dependent manner, both *in vitro* and *in vivo*. That the association occurs *in vivo* without the exogenous addition of thrombin indicates either that a subpopulation of circulating platelets is already expressing surface P-selectin, or that the tumor cells induce this expression, in cooperation with some other factors that are not present in the *in vitro* experiment. Regardless, the results support the notion that P-selectin-dependent formation of tumor:platelet clumps is a critical step in the process of metastasis formation. It does not, of course, rule out an additional role for P-selectin that might be expressed on the endothelial cells that make contact with tumor cells.

Unexpectedly, the primary flank tumors in P-selectin-deficient mice had a significantly slower growth rate. Occasional tumors even showed a partial regression and regrowth. This is particularly surprising because P-selectin is assumed to play a role in mediating extravasation of leukocytes into tissues and leukocytic infiltrates within tumors generally are inversely associated with tumor growth (46). Perhaps P-selectin does not play a dominant role in recruiting the chronic inflammatory infiltrate but has some other positive effect on tumor growth. Although others have suggested that SLEx-containing glycoconjugates may play a role in endothelial morphogenesis (47), we saw no obvious difference in the vascularization of tumors in P-selectin +/- and P-selectin +/+ mice. It is more likely that P-selectin is involved in recruiting leukocytes and/or platelets that secrete growth factors and cytokines meant for wound healing—these might unwittingly stimulate the growth of tumor cells.

P-selectin ligands have been detected previously on several human carcinomas and cell lines (37, 39, 40) and hypothesized to play a role in metastasis. These data show that endogenous P-selectin can affect the *in vivo* behavior of tumor cells. Indeed, this information potentially can bring together several disparate observations about carcinomas: (i) the proposed role of platelets in facilitating tumor metastasis; (ii) the suggested importance of tumor microemboli-containing platelets and leukocytes in this process; (iii) Trousseau’s syndrome, which occurs in patients with mucin-producing carcinomas and is associated with platelet-rich thrombemboli; (iv) the correlation of mucin production with poor clinical prognosis; and (v) the strong correlation of SLEx expression with tumor progression, metastatic spread, and poor prognosis. Our data indicate that the common link may be P-selectin and its interactions with SLEx-containing carcinoma mucins. We do not rule out additional roles for other selectins, because they also can recognize such mucins. Indeed, recent work from our lab indicates that each of the three selectins can have unique binding sites coexisting on a given carcinoma mucin molecule (Y.J.K., L.B., H. L. Han, N.M.V., and A.V., unpublished data).

Because P-selectin can be coexpressed on the endothelium with E-selectin and both can recognize SLEx antigens, both also could play a role in the homing of metastatic cells. However, only P-selectin provides a mechanistic connection involving platelets, which do not express L- or E-selectin.

One previous report showed that P-selectin recognizes sulfatides and theorized that the excretion of sulfatides might detach tumor cells from P-selectin-expressing cells such as the...
endothelium (34). Although this hypothesis may apply in other circumstances, it is not consistent with the protective effect of P-selectin deficiency seen here. Our data also indicate that cancer mucins mediate direct interactions of circulating platelets with intravenously injected tumors cells. Thus, we envisage that large mucin cores on the surface of tumor cells bearing multiple P-selectin-binding sites could bridge between tumor cells and P-selectin-expressing platelets and endothelium. The addition of leukocytes bearing PSGL-1 and/or L-selectin could favor the formation of the microemboli that are thought to aid the metastatic process (37).

In the final analysis, the precise mechanisms by which P-selectin facilitates tumor growth and progression remain to be defined. Regardless, we provide in vivo evidence that this cancer mucin–endothelial lectin interaction can have pathophysiological consequences. Because most relevant events occur and/or are initiated in the bloodstream, they are potentially amenable to intervention using anti-P-selectin therapeutics currently developed for modifying inflammatory and reperfusion injury states (31). In this regard, the clinically utilized antithrombotic agent heparin is a potent inhibitor of P-selectin binding to its natural ligand PSGL-1, at levels far lower than needed for its anticoagulant effects (48). Heparin and other sulfated compounds have been shown to block tumor metastases in some model systems (49–52), and mechanisms such as inhibition of heparanases, suppression of angiogenesis, and alteration of growth factor action have been suggested. Perhaps the ability of heparin to interfere with the interaction of P-selectin and tumor mucins also plays a major role in these antimitastatic effects.
